- Cloud mask threshold approaches rely on cloud-free skin temperature (T<sub>s</sub>) estimate
- *T<sub>s</sub>* in cloudy condition necessary for optical depth and height retrievals
- Downstream radiation budget calculations rely on clouds and on model T<sub>s</sub> in cloudy condition
- High variance in observed + model T<sub>s</sub> in all-sky conditions
- In GEO we estimate a cloud-free  $T_s$  with reasonably good accuracy using cloudfree observations, model 2-m air temperature  $(T_a)$ , and a deep neural network (DNN)

Can relationships between observed clear-sky  $T_s$  and modeled  $T_s+T_a$  help us estimate a more reliable all-sky  $T_s$ ?

- Highlight cloud-fraction-dependent relationships of:
  - Model *T<sub>s</sub>* and satellite *T<sub>s</sub>*
  - Model  $T_s$  and model  $T_a$
  - Model  $T_a$  and station  $T_a$
- Suggest paths toward an observation-linked all-sky T<sub>s</sub> solution
- Highlight GEO clear-sky T<sub>s</sub> DNN developments and explain limitations

~1/3 of land is "partly cloudy" – how to estimate an expected T<sub>s</sub> for all-sky conditions ?

## Model $T_s$ – Satellite $T_s$ Differences: Day

- 0% satellite cloud fraction at 0.5°x0.5°
- Pronounced, positive regional biases in GEOS-5.4.1 – broadly negative biases in GEOS-IT and ERA5
- Relatively comparable GEOS-IT and ERA5 biases, although still distinct (especially where often cloudy)

High daytime variance in regional  $T_s$  agreement between different models and satellites observations

## Model $T_s$ – Satellite $T_s$ Differences: Day

- For increasing satellite cloud fraction
- Would expect <u>cooler</u> daytime allsky model T<sub>s</sub> as cloudiness increases
- Daytime cloud contamination significantly impacting clear-sky observations in allsky grid tiles

No obvious correlation between regional biases and sample sizes (not shown)

## Model $T_s$ – Satellite $T_s$ Differences: Night

- For increasing satellite cloud fraction
- Would expect warmer nighttime all-sky model T<sub>s</sub> as cloudiness increases
- Warm bias tendency compounded by cloud contamination of clear-sky observations

Not *obvious* to conclude whether GEOS-IT is "better" than GEOS5.4.1, or if ERA5 is "better" than GEOS-IT

# Model $T_s$ – Satellite $T_s$ Differences: Summary

- All months share these tendencies, although with different offsets
- Driven primarily by imperfect cloud masking (highlights need?)
- GEOS-IT ERA5 relationship uninfluenced by cloud fraction

Variance <u>increases</u> with increasing cloud fraction

# Model $T_a$ – Model $T_s$ Differences: Day

- Can understanding model T<sub>a</sub>-T<sub>s</sub> relationships help inform reliable allsky T<sub>s</sub> estimates
- 0% <u>model</u> cloud fraction at 0.5°x0.5°
- Daytime 2-m T<sub>a</sub> significantly colder than T<sub>s</sub>, often where dry or mountainous

**GEOS-IT**  $T_a - T_s$  more often neutral than ERA5 difference, which is >5 K over much of world

# Model $T_a$ – Model $T_s$ Differences: Day

- For increasing model cloud fraction
- Tendency toward 0 K bias as cloudiness ↑
- GEOS-5.4.1 not often claiming 100% overcast

Clear  $\rightarrow$  overcast differences in model  $T_a - T_s$  may inform expected  $T_s$  bias in cloudy conditions

# Model $T_a$ – Model $T_s$ Differences: Night

- Clear-sky bias patterns cover similar regions, but reverse of day
- Same tendency toward neutral bias with ↑ clouds
- Models provide allsky T<sub>s</sub> for a grid tile, but we don't have global all-sky ground truth

Can we interpret model clear  $\rightarrow$  overcast  $T_a - T_s$ relationships to produce a more accurate cloudy  $T_s$ ?

### Model $T_a$ – Station $T_a$ Differences

- We know model-satellite clear-sky consistency is poor
- With station data, we can test model  $T_a$  consistency for clear  $\rightarrow$  overcast

**Overcast model-station consistency** about the same as that for clear

# Model $T_a$ – Model $T_s$ Differences: Summary

- As clear  $\rightarrow$  overcast,  $T_s \rightarrow T_a$
- True, on average, for all months, day and night
- Variance <u>decreases</u> with increasing cloud fraction
- Anchor clear-sky satellite estimates to curves in a model – later tie in optical thickness estimate

A good first-order assumption?

### Clear-sky T<sub>s</sub> DNN Estimates: Day

- Clear-sky DNN T<sub>s</sub> estimates should be minimally affected by cloud contamination
- Trace cloud contamination where especially cloudy may have influenced training data (a)
- May explain why

   (a) weighted bias
   does not decrease
   further with ↑
   cloud fraction

**GEO DNN** *T<sub>s</sub>* value may be a more reliable clear-sky estimate than observations when partly cloudy

### Clear-sky T<sub>s</sub> DNN Estimates: Night

- Expect (a) to warm as emitted cloud radiance increases in the model
- Immediately offset by increased dominance of cloudy high elevation regions
- Cloudy mountains seemingly modeled colder than satellite measurements

Nighttime GEO DNN *T<sub>s</sub>* also appears to dodge cloud contamination issue

## Clear-sky T<sub>s</sub> DNN Summary

CERES

 For daytime (a), trace cloud contamination initially, then model temperature drops

 For nighttime (a), immediate influence from cold mountainous regions, then thermal emittance strengthens

Patterns are consistent across seasons

- Models deviate significantly from observed surface temperatures in all clear/cloudy conditions
- Satellite-based clear-sky T<sub>s</sub> estimates can help produce a more regionally consistent cloud mask
- There is no global ground truth for all-sky/overcast conditions
- Maybe good enough to just use ERA5 because of assimilation practices, but not available in CERES – still shows satellite-relative bias like other models
- Perhaps tendency for  $T_s \rightarrow T_a$  as clear  $\rightarrow$  overcast is a good first-order assumption for improving all-sky  $T_s$  (anchored to expected satellite clear-sky  $T_s$ )
- Clear-sky DNN  $T_s$  estimates are a good starting point for testing this effort

# **Additional Slides**

#### Model $T_s$ – Satellite $T_s$ Differences: Samples

No obvious correlation between regional biases and sample sizes

## Model $T_s$ – Satellite $T_s$ Differences: Night

- 0% satellite cloud fraction at 0.5°x0.5°
- Overall more neutral, but all models show strong regional biases
- GEOS-IT and ERA5 have greater similarity than during the day

Whether day or night, not *obvious* to conclude if GEOS-IT is "better" than GEOS5.4.1, or if ERA5 is "better" than GEOS-IT

# Model $T_a$ – Model $T_s$ Differences: Night

- Clear-sky bias patterns cover similar regions, but reverse of day
- Same tendency toward neutral bias with ↑ clouds
- Models provide allsky T<sub>s</sub> for a grid tile, but we don't have global all-sky ground truth

Can we interpret model clear  $\rightarrow$  overcast  $T_a - T_s$ relationships to produce a more accurate cloudy  $T_s$ ?

#### Model $T_s$ – Model $T_a$ Differences

Model T<sub>s</sub> and T<sub>a</sub> are reasonably close in overcast conditions at surface sites

### Clear-sky T<sub>s</sub> DNN Developments/Limits

#### • Previous DNN:

- Predictors: GEOS-IT T<sub>a</sub>, Latitude, Longitude, Local Time, SZA, IGBP, day-of-year, and snow flag
- Skillful on average, regional biases strongly tied to model biases (suggests data representation issue)
- New DNN:
  - Substitutes month for day-of-year
  - Adds water percentage and GEOS-IT cloud fraction
  - Better engineered training/validation/testing splitting
  - An improvement, but persistent representation issue suggests more years of training data are necessary
